(Received 19 July 1989)

The electronic structure of amorphous silicon models has been calculated with the tight-binding parameters of Chadi. An energy gap of ~ 1.0 eV is obtained for a fully four-coordinated model, whereas gap states occur for models with coordination defects. Dangling-bond gap states are well localized on the three-coordinated site. Floating bonds lead to considerably less localized gap states with wavefunction amplitudes on the neighbors of the five-coordinated atom. The hyperfine splittings of these coordination defects are calculated and compared to experiment.

PACS numbers: 71.25.Mg, 61.40.+b

The dominant paramagnetic defect in amorphous silicon (*a*-Si) has been commonly believed to be the dangling bond. Recently, Pantelides proposed that the floating bond or five-coordinated silicon atom is an equally viable native defect in *a*-Si.^{1,2}

However, Phillips³ has argued that the growth kinetics of *a*-Si films is unfavorable for overcoordination defects, but should instead favor dangling bonds as the dominant defect. Stutzmann and Biegelsen⁴ observed that the ²⁹Si hyperfine data are completely consistent with the dangling-bond model. Based on defect-state wave functions and energies for Bethe-lattice-terminated nine-atom Si clusters, Fedders and Carlsson^{5,6} inferred that the ESR signal in *a*-Si:H arises from dangling bonds.

In this paper, we wish to clarify the controversy between the dangling and floating bonds by calculating their electronic properties and presenting new results on the differences between these two types of coordination defects that should be useful for the interpretation of experimental data. Structural models containing both dangling and floating bonds have been derived by Biswas, Grest, and Soukoulis⁷ (BGS) from molecular-dynamics simulations of the quenching of a melt of bulk Si. In contrast to previous calculations,^{5,6} we do not ascribe a specific structural geometry to the floating bond, but instead allow it to assume an energetically favorable configuration consistent with the amorphous network topology. To meaningfully extract properties of the coordination defects, we have also performed calculations for the Monte Carlo *a*-Si model generated by Wooten, Winer, and Weaire^{8,9} (W3), in which all atoms have a coordination of four.

The electronic-structure calculations were performed with a nearest-neighbor tight-binding model consisting of the minimal basis of one *s* and three *p* Si orbitals and the tight-binding parameters derived by Chadi.¹⁰ The Chadi tight-binding model has been extensively used to study structural, electronic, and vibrational properties of crystalline Si and Si(111) and Si(100) surfaces with much success. We have incorporated the standard $1/d^2$ scaling of the interatomic matrix elements, together with a bond

cutoff that is between the first and second peaks of the radial distribution function $g(r)$ of the *a*-Si models. The interatomic interaction is described by the sum of the electronic band-structure energy, and a repulsive two-body potential is derived¹¹ by subtracting the band-structure energy from accurate first-principles total-energy calculations for the diamond Si structure.¹²

The atomic positions obtained by the classical W3 and BGS models (216 atoms) were used as input for the tight-binding electronic-structure approach and the positions were then relaxed to the lowest energy. Within the Chadi parametrization, a well-defined gap of ~ 1.0 eV exists for the four-coordinated relaxed W3 model (see Fig. 1). The valence density of states (DOS), especially the position of the *p* peak and the bandwidth, is in very good agreement with photoemission measurements.¹³ The conduction band, however, is not given accurately from Chadi's scheme, but this is less important for our studies. In contrast to the W3 case, the relaxation of the BGS atomic positions substantially reduced the gap DOS from the structure obtained with the unrelaxed po-

FIG. 1. Electronic densities of states for the W3 model (solid line) compared to the BGS model (broken line). All sites of the W3 model have coordination four, whereas the BGS model has three- and five-coordinated atoms.

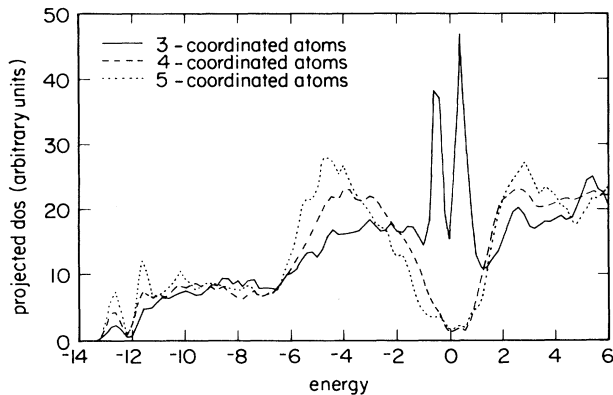

FIG. 2. Projected electronic densities of states on three-, four-, and five-coordinated atoms in the BGS model.

sitions.⁷ After this relaxation step, the BGS model had twelve dangling bonds and four floating bonds.

We find that the DOS in the gap region arises from either (i) dangling bonds, (ii) floating bonds, or (iii) strongly disordered four-coordinated sites. The projected DOS on sites of different coordination (Fig. 2) displays the large contributions of dangling bonds to the gap states. Within the Chadi model, neutral (D^0), negatively charged (D^-), and positively charged (D^+) dangling-bond states exist. The relative positions of these charge states cannot be determined reliably with the present scheme, although the D^0 , D^- , and (D^+) levels comprise the lower (upper) peaks. Since the Chadi parameters can overemphasize charge-transfer effects, a Hubbard on-site repulsion (U) of 1.0 eV was used in the calculations of Fig. 2, similar to previous calculations for the Si(111) surface.¹⁴

The wave functions of the dangling bonds are very strongly localized. We found two strongly localized midgap states in each of which $\sim 57\%$ of the wave function was centered on the dangling bond, together with very small amplitudes on neighboring atoms [Fig. 3(a)]. The finite size of our α -Si model resulted in the hybridization among dangling-bond states. Interactions between defects in finite-size models have been noted in previous work.¹⁵ To isolate individual dangling bonds, we introduced "terminator" atoms on all dangling bonds except the one being studied. The terminators had a single s orbital with a site energy $E_s = 0$ and the same ss and sp interactions as in Si. The terminators played a role similar to H in α -Si:H in reducing gap states and opening a gap of 0.45 eV in our model. This led to gap states in which 40%–50% of the wave function was localized on individual dangling bonds. These strongly localized dangling-bond states are consistent with ESR results.

Saturating all dangling bonds in our model with terminator atoms removes the interactions between dangling and floating bonds among the gap states. Each of the four floating bonds in the model lead to a separate state either in the valence-band tail or in the gap region. In each of these states (Table I), the amplitude of the wave function is vanishingly small on the central five-coordinated atom, but is dis-

tributed over 3–5 four-coordinated neighbors of the five-coordinated atom. More than half of the wave function is delocalized outside this six-atom cluster. The anisotropic nature of the wave function can be observed in Fig. 3(b). These conclusions are consistent with the results of Fedders and Carlsson^{5,6} for canonical floating-bond configurations.

These results for the floating-bond wave function are physically plausible, since the four sp^3 hybrids on the five-coordinated atom should be occupied. The extra floating bond then leads to an unpaired electron spin on the neighboring atoms. Our results indicate this unpaired electron is somewhat delocalized and can resonate between three or four of the neighbors. We stress that the picture of the floating bond consisting of a single dominant site involving an unpaired electron spin with one secondary atom¹⁶ is inconsistent with our results.

A significant difference in the structural geometry at the five-coordinated sites in our α -Si model and the "ideal" floating-bond configuration is the absence of three collinear atoms. The 180° bond angle associated with the collinear geometry generates considerable angular strain which is relieved by a lower-symmetry structural distortion.

Electron-spin-resonance spectra¹⁷ in α -Si:H indicate a hyperfine line with a splitting of ~ 74 G from the central ESR signal, arising from the interaction of an unpaired electronic spin with a ^{29}Si nuclear spin. The hyperfine

data have been interpreted as evidence both for¹⁶ and against¹⁸ the floating-bond configuration. We examine the hyperfine splitting expected in our model, which is given by

$$\Delta H = \left[\frac{16\pi}{3} \right] \left[\frac{\mu_j}{I_j} \right] \mu_B \alpha_j^s \eta_j^s |\psi_{3s}(0)|^2. \quad (1)$$

Here μ_j and I_j are the nuclear magnetic moment and nuclear spin of ^{29}Si . μ_B is the Bohr magneton. α_j , β_j , and η_j are the s and p components and amplitudes of the electronic wave function on site j defined by $|\psi\rangle = \sum_j \eta_j (\alpha_j |s_j\rangle + \beta_j |p_j\rangle)$, with $\alpha_j^2 + \beta_j^2 = 1$. They are given in Table I. We adopted the value of $31.5 \times 10^{-24} \text{ cm}^{-3}$ from Ref. 19 for the electronic valence s wave function at the nuclear site.

The floating-bond wave functions have large s components α_j . Although the individual amplitudes η_j on the sites surrounding the five-coordinated atom are small, a substantial product $\alpha_j^s \eta_j^s$ is possible, resulting in a distribution of hyperfine splittings between ~ 25 G and 67 G (Table I). This leads to an overall broadening of the ESR line, rather than a sharp hyperfine feature. The distribution of hyperfine splittings arises from the delocalized nature of the floating-bond wave function.

The s and p characters of the dangling bonds are very sensitive to the structural geometry. In our α -Si model, the dangling bonds are mostly p -like with α_j^s between 0.001 and 0.05, which leads to very small hyperfine split-

tings. Results for the other dangling bonds are very similar to the representative results in Table I. This is in direct contrast to the Si(111) surface dangling bonds, where the s character is much larger, with α_j^2 varying from 0.19 for the unreconstructed case to ~ 0.10 for an inward surface relaxation of 0.53 Å (Table I). The surface calculations were also performed with the present tight-binding model which, in fact, energetically favors the unrelaxed Si(111) configuration rather than a more planar geometry. The reduced s character of the a -Si-model dangling bonds is due to large bond-angle distortions at these sites [e.g., Fig. 3(a)]. We emphasize that both strong localization as well as substantial s character is needed to account for the hyperfine spectra. One interpretation is that the observed hyperfine spectra could arise from a class of dangling bonds that have a narrow structural distribution very similar to the Si(111) surface. Such dangling bonds may occur on the surfaces of microvoids.

Finally, strongly disordered four-coordinated atoms in both the BGS and W3 model give rise to DOS peaks in the valence-band tail. These states emerge in DOS projected on individual atoms and are relatively insensitive to the presence of terminator atoms. Four-member rings of atoms, that have large bond-angle deviations, lead to states in the valence tail (between -0.8 and -0.6 eV). Individual atoms with large bond-angle deviations $\Delta\Theta_{\text{rms}}$ exceeding 25° [see Fig. 3(c)], or weak Si-Si bonds, lead to states that are less localized than either the dangling- or floating-bond states. The large structural distortions pull out bonding and antibonding states from the valence and conduction bands and bring them towards midgap, resulting in band-tail states.

In conclusion, floating bonds have substantially less localized wave functions than dangling bonds. Their wave functions are centered on the neighbors of the five-coordinated atom giving rise to a distribution of hyperfine splittings.

We note, however, that there may be kinetic factors that do not favor five-coordinated atoms. In previous work,²⁰ we found that introduction of microvoids in a -Si networks decreased by an order of magnitude the number of floating bonds. This is due to the ability of the floating bonds to diffuse easily and reach an internal surface, where they could recombine with dangling bonds. Discussion of such kinetic factors is an aspect for further study.
